arXiv:0805.3045v3 [hep-ph] 16 Sep 2008

Abstract

The effects of flavor mixing in electroweak baryogenesis is investigated in a generalized semiclassical WKB approach. Through calculating the nonadiabatic corrections to the particle currents it is shown that extra CP violation sources arise from the off-diagonal part of the equation of motion of particles moving inside the bubble wall. This type of mixing-induced source is of the first order in derivative expansion of the Higgs condensate, but is oscillation suppressed. The numerical importance of the mixing-induced source is discussed in the Minimal Supersymmetric Standard Model and compared with the source term induced by semiclassical force. It is found that in a large parameter space where oscillation suppression is not strong enough, the mixing-induced source can dominate over that from the semiclassical force.

I. INTRODUCTION

Electroweak baryogenesis (EWBG) is a promising scenario for explaining baryon number asymmetry in the universe, unlike other scenarios valid at grand unification scale it can be tested by the upcoming collider experiments. The Standard Model (SM) of particle physics due to the too small CP violation [1, 2, 3, 4] and difficulty in generating a strongly first order phase transition [5, 6, 7] can not be a candidate for baryogenesis. However, EWBG is viable in many new physics models beyond the SM such as Minimal Supersymmetric Standard Model (MSSM) [8, 9, 10] and the two-Higgs-doublet models [11, 12, 13, 14, 15, 16, 17, 18] etc, as in these models there are extra particles contributing to the Higgs potential and also new sources of CP violation.

An efficient way to generate large baryon number asymmetry is to generate it nonlocally, through a charge transportation mechanism [19, 20, 21] in which the CP violating charges are first generated inside the bubble wall and then get transported into the unbroken phases, where the anomalous baryon number violating sphaleron processes are not suppressed. In some models such as MSSM and the two-Higgs-doublet model, the bubble wall of the electroweak phase transition is typically thick [22, 23] for the particles giving dominant contributions, and the particle typical Compton wave length $\lambda \sim 1/T$ is much shorter than the wall width $L_w \sim (10-20)/T$ where T is the critical temperature. In this regime the validity of semiclassical approach [24, 25, 26, 27, 28, 29, 30, 31] should be justified for single flavor case, which provides an intuitively simple description by treating particle transportation as motion of WKB wave packages. In a slowly moving and CP violating Higgs condensate background, the dispersion relation for particles and antiparticles are modified differently, contributing to different semiclassical forces, which leads to a net excess or deficit of the particle number which can be converted into left-handed fermion number asymmetry. The asymmetry of the local fermion density then get transported in front of the bubble wall, which bias the baryon number violating processes.

The problem becomes more involved in the multiple flavor case, where the CP violating mass matrix has nontrivial space-time dependence. The CP violating effects may show up not only in the dispersion relations, but also in the mixing of states. In the conventional WKB approach [24, 25, 31] the particle propagation is treated as an adiabatic motion: the quasiparticles are first rotated into the local mass eigenstates, then these particles are assumed to evolve individually without interference. The semiclassical force terms are identified for each individual states as the unique CP violating source for the diffusion equations. However, note that in many cases such as in MSSM, the quasiparticles do not decouple even in the local mass basis, because the rotation matrices diagonalizing the mass matrix are also spatially varying, which leads to interferences among the local mass eigenstates. Namely, there always exists nonvanishing off-diagonal terms in the equations of motion. The off-diagonal terms in the equation of motion lead to nonconservation of net currents, which contributes to extra CP violating source terms. Such a contribution can be numerically important, because the semiclassical force term is of the second order in derivative expansion, and is further suppressed to the third order when entering the semiclassical diffusion equations as a source term, while the mixing-induced source presents from the first order.

The problem of spatially dependent mixing has been discussed in the non-equilibrium field theory approach based on the Kadanoff-Baym equations for Wigner transformed Green functions [34, 35]. It has been noticed recently that the evolution of the off-diagonal densities from the transverse part of the constraint equation exhibit oscillation behavior, which is quite different from the diagonal densities [32, 33]. Other methods although using the same Schwinger-Keldysh formalism treat the problem in different manner, such as using the Higgs condensate insertion [36, 37, 38] or applying re-summation for Higgs condensate insertion but using phenomenological ways to deal with the source terms [39]. The final result still differ significantly, especially in the bosonic sector.

In view of the current theoretical situation, a carefully reanalysis of the semiclassical method may still be useful. In this work we generalize the semiclassical method by taking into account the non-adiabatic corrections from the spatially varying flavor mixings. We restrict ourselves in the parameter region where the mixing between the local mass eigenstates are relatively small, and can be treated as perturbations to the equation of motion for local mass eigenstates. Our results show that the correction leads to an extra CP violating source which exhibit a typical oscillation behavior in analogy to neutrino oscillations, which is similar to the observations made in [32]. We go a step further to estimate the source term and compare it with the semiclassical forces in the context of MSSM. The results show that despite the oscillation suppression, the mixing-induced source term has significant numerical importance for a large parameter space.

II. THE FERMIONIC CASE

We begin with a brief review of the semiclassical description for fermions in a expanding planar bubble wall. For simplicity the fermion is boosted into a wall frame in which the momentum parallel to the wall is vanishing. In this case the equation of motion is reduced to 1+1 dimensional, and in flavor basis it is given by

$$[i(\gamma_0\partial_t + \gamma_3\partial_z) - M^\dagger(z)P_L - M(z)P_R]\psi = 0 \tag{1}$$

where $M(z)$ is the spatial varying mass matrix from a mass term $\bar{\psi}_L M(z)\psi_R$ induced by a slowly moving Higgs condensate, and $P_{L,R} = (1 \mp \gamma_5)/2$ the chirality projection operator. The wave function in the chiral representation of Dirac matrices can be decomposed in terms of spin eigenstates

$$\psi_s = e^{-i\omega t}\begin{pmatrix} L_s \\ R_s \end{pmatrix} \otimes \chi_s \tag{2}$$

with $\sigma_3\chi_s = s\chi_s$ and $s = \pm 1$ for two spin states. $L_s(R_s)$ is the left- (right-) handed component. Substituting ψ_s into Eq.(1) and eliminating the right-(left-) handed component one obtains the equation for $L_s(R_s)$ in flavor basis

$$\begin{aligned}
\left[\omega^2 + \partial_z^2 - MM^\dagger + isM\partial_z M^{-1}(\omega - is\partial_z)\right] L_s &= 0 &(3)\\
\left[\omega^2 + \partial_z^2 - M^\dagger M - isM^\dagger\partial_z M^{\dagger -1}(\omega + is\partial_z)\right] R_s &= 0 &(4)
\end{aligned}$$

One can rotate the fields into a local mass basis (L_s^d, R_s^d) by defining $L_s = UL_s^d$ and $R_s = VR_s^d$ in which the mass matrix $M(z)$ is diagonalized $U^\dagger M(z)V = m(z)$ with $m(z)$ a diagonal mass matrix. The phases of U and V are arranged such that the mass eigenvalues m_i are real positive. Note that both U and V are z dependent. The equation of motion for local mass eigenstates L_s^d and and R_s^d becomes

$$\begin{aligned}
i(\partial_t - s\partial_z - sU^\dagger\partial_z U)L_s^d - mR_s^d &= 0 &(5)\\
i(\partial_t + s\partial_z + sV^\dagger\partial_z V)R_s^d - mL_s^d &= 0 &(6)
\end{aligned}$$

It is evident that the equation for right-handed component in the local mass basis can be obtained by replacing $U \rightarrow V$ and $s \rightarrow -s$. Following the similar step in obtaining Eq.(4) one arrives at the decoupled second order equations

$$\begin{aligned}
\left[\omega^2 + \partial_z^2 - m^2 + 2\Sigma\partial_z + isA(\omega - is\partial_z)\right] L_s^d &= 0 &(7)\\
\left[\omega^2 + \partial_z^2 - m^2 + 2\Pi\partial_z - isB(\omega + is\partial_z)\right] R_s^d &= 0 &(8)
\end{aligned}$$

where

$$\Sigma = U^\dagger \partial_z U \ \ , \ \ A = U^\dagger M \partial M^{-1} U \tag{9}$$

$$\Pi = V^\dagger \partial_z V \ \ , \ \ B = V^\dagger M^\dagger \partial M^{\dagger -1} V \tag{10}$$

In the above equations the terms of second order in derivative expansion are neglected. The off-diagonal elements of A and B are related to Σ and Π through

$$A_{ij} = \frac{m_i}{m_j}\Pi_{ij} - \Sigma_{ij} \ \ , \ \ B_{ij} = \frac{m_i}{m_j}\Sigma_{ij} - \Pi_{ij} \ \ (\text{ for } i \neq j)$$

In the remainder of this section we shall suppress the index "d" in the wave function. In two flavor mixing case the explicit form of the equation array for left-handed component can be rewritten as

$$\begin{pmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{pmatrix} \begin{pmatrix} L_{s1} \\ L_{s2} \end{pmatrix} = 0 \tag{11}$$

with

$$\begin{aligned} D_{11} &= \omega^2 + \partial_z^2 - m_1^2 + 2\Sigma_{11}\partial_z + isA_{11}(\omega - is\partial_z) && (12) \\ D_{12} &= 2\Sigma_{12}\partial_z + isA_{12}(\omega - is\partial_z) && (13) \\ D_{21} &= 2\Sigma_{21}\partial_z + isA_{21}(\omega - is\partial_z) && (14) \\ D_{22} &= \omega^2 + \partial_z^2 - m_2^2 + 2\Sigma_{22}\partial_z + isA_{22}(\omega - is\partial_z) && (15) \end{aligned}$$

Since the off-diagonal elements $D_{12(21)}$ contain differential operators, one can not obtain decoupled equations for $L_{s1(2)}$ separately. In the conventional approach [25], the equation array is solved approximately by first imposing the derivative operator $D_{22(11)}$ on the first (second) row of Eq.(11) once again, then picking up the terms up to the first order derivative, which leads to equations containing higher order derivatives $D_{ii}D_{jj}L_{sj} \simeq 0 (i \neq j)$ and finally argue that they reduce to a decoupled form

$$D_{ii}L_{si} = 0, \tag{16}$$

which is essentially the diagonal part of Eq.(11). Note that in this method the off diagonal terms are counted as higher order terms and thus neglected. An advantage of this method is that it naturally allows an adiabatic description of the motion of individual particles.

However, It is clear that Eq.(16) misses the information from off-diagonal term $D_{12,21}$, which is only valid when $|D_{12,21}| \ll |D_{11} - D_{22}|$. In large mixing case it is not a good approximation to Eq.(11).

To investigate the impact of the off-diagonal terms, in this work we adopt an alternative method to solve Eq.(11) approximately. We are interested in the parameter region in which the off-diagonal elements is non-negligible but relatively small such that it can be treated as perturbations. The validity of the perturbation requires that the mass difference between the two mass eigenstates are significantly larger than the mixing term, namely $\partial_z m \ll \left|m_i^2 - m_j^2\right|$, where m is the averaged mass. Although this method does not apply to the resonance case $\left|m_i^2 - m_j^2\right| \simeq 0$, it should illustrate the main feature of the mixing caused by off-diagonal term D_{ij}.

Taking the off-diagonal terms D_{12} and D_{21} as perturbations. The solutions can be written in a generic form

$$L_{si} = L_{si}^{(0)} + L_{si}^{(1)} \tag{17}$$

where $L_{si}^{(0)}$ is the lowest order solution satisfying Eq.(16), i.e.

$$D_{ii} L_i^{(0)} = 0 \tag{18}$$

and $L_{si}^{(1)}$ are the corrections due to the off-diagonal terms. The lowest order solution $L_{si}^{(0)}$ is obtained by the usual WKB wave ansatz

$$L_{si}^{(0)} = w_i e^{i\int^z p_{ci}(z')dz'}$$

where p_{ci} is the canonical momentum and the function w_i provides the correct normalization for $L_{si}^{(0)}$. The real and imaginary part of Eq.(18) lead to two separated equations

$$\begin{aligned} \omega^2 - p_{ci}^2 - m_i^2 &= \mathrm{Im}\left[2p_{ci}\Sigma_{ii} + s(\omega + s p_{ci})A_{ii}\right] && (19) \\ p'_{ci} + 2p_{ci}\frac{w'_i}{w_i} &= \mathrm{Re}\left[2p_{ci}\Sigma_{ii} + s(\omega + s p_{ci})A_{ii}\right] && (20) \end{aligned}$$

where the notation prime stands for the spatial derivative ∂_z. The first equation gives the dispersion relation

$$p_{ci} \simeq p_0 - \frac{s(\omega + s p_0)}{2p_0}\mathrm{Im}A_{ii} - \mathrm{Im}\Sigma_{ii} + \alpha' \tag{21}$$

where α is an arbitrary phase factor from gauge invariance [27]. From the dispersion relation one can deduce the group velocity $v_g \equiv (\partial\omega/\partial p_c)_z$ and semiclassical force $F_i \equiv \omega(dv_g/dt)$

$$v_{gi} = \frac{p_{0i}}{\omega} - s\frac{m_i^2 \mathrm{Im}A_{ii}}{2\omega^2 p_{0i}} \tag{22}$$

$$F_i \; = \; -\frac{m_i m_i'}{\omega} - s\frac{(m_i^2 \mathrm{Im} A_{ii})'}{2\omega^2} \tag{23}$$

Note that only the second term in the force term is CP violating, and is proportional to the spin of the local mass states. Together with the lowest order solution to w_i from the second equation, the wave function at the lowest order is given by

$$L_i^{(0)} \; = \; \frac{m_i}{\sqrt{p_{0i}(\omega + s p_{0i})}} e^{i\int^z p_{ci} dz'}, \text{ and } R_i^{(0)} = \frac{m_i}{\sqrt{p_{0i}(\omega - s p_{0i})}} e^{i\int^z p_{ci} dz'} \tag{24}$$

with $p_{0i}^2 = \omega^2 - m_i^2$.

Substituting the off-diagonal terms in to the equation, the first order perturbation takes the following form

$$L_{si} \; \simeq \; L_{si}^{(0)} + L_{si}^{(1)} = L_{si}^{(0)} + \epsilon_i L_{si}^{(0)} \tag{25}$$

$$R_{si} \; \simeq \; R_{si}^{(0)} + R_{si}^{(1)} = R_{si}^{(0)} + \delta_i L_{si}^{(0)} \tag{26}$$

which are mixtures of the two unperturbed states. The mixing parameters for particle i to the first order of derivative are given by

$$\epsilon_i = i\frac{2\Sigma_{ij} p_{0j} + A_{ij}(s\omega + p_{0j})}{m_i^2 - m_j^2}, \text{ and } \delta_i = i\frac{2\Pi_{ij} p_{0j} + B_{ij}(-s\omega + p_{0j})}{m_i^2 - m_j^2} \tag{27}$$

The mixing parameters for particle j can be simply obtained by replacing $i \leftrightarrow j$ from the above expressions. It is clear that the expansion is valid for $\partial_z m_i/(\Delta m^2) \ll 1$ as expected. The momentum dependencies comes from the differentiation operators in off-diagonal element D_{12}.

During the particle propagation inside the bubble wall, the Higgs condensate background causes mixing between the two local mass states, which keeps the total particle current conserved but leads to nonconservation of the currents for individual particles. The nonvanishing divergence of the current caused by the off-diagonal part of spatially varying rotation matrix is proportional to the mixing parameters ϵ_i and δ_i, which are different for particle and antiparticle when the mixing contains CP violation. This provides an extra CP violating source other than the semiclassical force. Note that the mixing term modifies the dispersion relation as well. As it contains derivative terms, it implies the breaking down of the semiclassical picture. However, this is a next to leading order correction to the dispersion relation and is expected to be small.

As an illustration, we calculate the left-handed current divergence. The temporal and spatial part of the left-handed current are $j^0 = L_s^* L_s$ and $j^z = -sL_s^* L_s$ respectively. The mixing parameters for the antiparticle can be obtained by replacing $\Sigma \to \Sigma^*, A \to A^*, \Pi \to \Pi^*$, and $B \to B^*$. The mixing-induced left-handed current, after subtracting the antiparticle component is given by

$$j_{Li}^z = -\frac{4m_i m_j}{m_i^2 - m_j^2} \frac{2s\mathrm{Im}\Sigma_{ij} p_{0j} + \mathrm{Im}A_{ij}(\omega + sp_{0j})}{\sqrt{p_{0i}p_{0j}(\omega + sp_{0i})(\omega + sp_{0j})}} \cos \int^z (p_{cj} - p_{ci}) dz' \tag{28}$$

The CP violating force term, as it is proportional to spin s, only contribute to the spin-weighted density. To facilitate the comparison with the force term, we calculate the spin-weighted mixing-induced source term. Indeed, it has been pointed out that only spin-weighted current is sourced by the moving wall [32]. In the wall frame, the corresponding source term for the left-handed current is

$$S_{Li} = \sum_s \frac{s}{2} \partial_\mu j_{Li}^{s\mu} \tag{29}$$

$$= \frac{2m_i m_j}{m_i^2 - m_j^2} \left[\mathrm{Im}\Sigma g_L(p_{0i}, p_{0j}) - \frac{m_i}{m_j} \mathrm{Im}\Pi_{ij} g_R(p_{0i}, p_{0j}) \right] \tag{30}$$

$$\cdot (p_{0i} - p_{0j}) \sin \int^z (p_{cj} - p_{ci}) dz' \tag{31}$$

with

$$g_{L,R}(p_{0i}, p_{0j}) = \frac{\omega \mp p_{0j}}{\sqrt{p_{0i}p_{0j}(\omega + p_{0i})(\omega + p_{0j})}} - \frac{\omega \pm p_{02}}{\sqrt{p_{0i}p_{0j}(\omega - p_{0i})(\omega - p_{0j})}} \tag{32}$$

which is a momentum odd function.

The numerical importance of the source term comes from the fact that it is of the first order in derivative expansion, larger than that from semiclassical force which is of the second order. Furthermore, The final form of the semiclassical force term entering the semiclassical diffusion equation is of the third order in derivative as it is weighted by group velocity. While in the diffusion equation, the mixing-induced source term is not suppressed. Therefore in a naive counting, one expects a much larger contribution from mixing induced source term.

What might significantly suppress the mixing-induced source is the oscillation. A crucial feature is that the oscillation frequency depends on the momentum *difference* rather than the momentum themselves, which makes the oscillation suppression less effective for relatively small momentum differences. From Eq.(31), the oscillation term can be approximated by $\sin(p_{02} - p_{01})dz$ at the lowest order. In a highly relativistic limit the oscillation wave length

λ_{osc} is given by

$$\frac{1}{\lambda_{osc}} \simeq \frac{m_1^2 - m_2^2}{4\pi\omega}$$

which is well-known for neutrino oscillations. For an illustration, taking $\omega \simeq 300$ GeV, $m_1 \simeq 200$GeV and $m_2 \simeq 100$ GeV, we find λ_{osc} is around $\mathcal{O}(0.1\text{GeV}^{-1})$ which is much larger than the typical Compton wave length $1/T$. Thus the oscillation is unlikely to completely erase the mixing-induced source.

Finally, The source is proportional to the off-diagonal elements of Σ_{ij} and Π_{ij}, which is different from the CP violating source term which is always proportional to the diagonal elements A_{ii}. This leads to a different parameter dependence in the final source term.

III. THE BOSONIC CASE

The mixing in bosons can be calculated in a similar way. The Klein-Gordon equation in flavor basis is

$$\partial^\mu \partial_\mu \phi + M^2(z)\phi = 0 \tag{33}$$

where $M^2(z)$ is the mass square matrix which is diagonalized by a unitary transformation $U^\dagger M^2(z) U = m^2(z)$. Rotating ϕ into the local mass basis with $\phi = U\phi^d$, the equation of motion for ϕ^d in the wall frame has the form

$$\partial_t^2 \phi^d - \partial_z^2 \phi^d + 2U^\dagger \partial^z U \partial_z \phi^d + m^2 \phi^d = 0 \tag{34}$$

We shall suppressed the index "d" in the remainder of this section. In the two flavor mixing case the above equation can be rewritten in a matrix form

$$\begin{pmatrix} D_{11} & D_{12} \\ D_{21} & D_{22} \end{pmatrix} \begin{pmatrix} \phi_1 \\ \phi_2 \end{pmatrix} = 0 \tag{35}$$

The operators D_{ij} are given by

$$D_{11} = \partial^2 + m_1^2 + 2\Sigma_{11}\partial_z \tag{36}$$

$$D_{12} = 2\Sigma_{12}\partial_z \tag{37}$$

$$D_{21} = 2\Sigma_{21}\partial_z \tag{38}$$

$$D_{22} = \partial^2 + m_2^2 + 2\Sigma_{22}\partial_z \tag{39}$$

with $\Sigma \equiv U^\dagger \partial_z U$. Again we solve the equation by taking off-diagonal elements $D_{12(21)}$ as perturbations. The solution takes the form

$$\phi_i = \phi_i^{(0)} + \phi_i^{(1)} \tag{40}$$

with $\phi_i^{(0)}$ satisfying the lowest order equations

$$D_{ii}\phi_i^{(0)} = 0 \tag{41}$$

Making use of the WKB ansatz

$$\phi_i^{(0)} = w_i e^{-i\omega t} e^{i\int^z p_{ci}(z')dz'} \tag{42}$$

and substituting it into the Eq.(41), the real and imaginary part gives two independent equations

$$\begin{aligned} -\omega^2 + p_{ci}^2 + m_i^2 - ip'_{ci} + 2\mathrm{Im}\Sigma_{ii} \cdot p_{ci} &= 0 \qquad (43) \\ -p'_{ci} + 2\frac{w'}{w}p_{ci} + 2\mathrm{Re}\Sigma_{ii} \cdot p_{ci} &= 0 \qquad (44) \end{aligned}$$

The first equation indicates the modification of dispersion relation. An important difference from the fermionic case is that the dispersion relation for scalar fields will not generate the semiclassical force at the first order in derivative expansion because the contribution from $\mathrm{Im}\Sigma$ cancels in the expression for dv_g/dt. The second equation determines the form of w. To the lowest order $w_i \simeq 1/\sqrt{p_{ci}}$. Taking the mixing term D_{ij} as perturbations, the solution takes the form

$$\phi_i \simeq \phi_i^{(0)} + \epsilon_i \phi_j^{(0)}, \tag{45}$$

the mixing coefficient to the first order in derivative is

$$\epsilon_i = i\frac{2\Sigma_{ij}p_{jc}}{m_i^2 - m_j^2} \tag{46}$$

The mixing parameter for particle j can be obtained by replacing $i \leftrightarrow j$ in the above expression. The spatial component for the current is $j_i^z = i(\phi_i^*\partial^z\phi_i - \partial^z\phi_i^*\phi_i)$. Substitute the expression of ϕ_i the mixing-induced current is given by

$$j_i^z = i(\epsilon\phi_i^{(0)*}\partial\phi_j^{(0)} - \epsilon^*\partial\phi_j^{(0)*}\phi_i^{(0)}) + i(\epsilon^*\phi_j^{(0)*}\partial\phi_i^{(0)} - \epsilon^*\partial\phi_i^{(0)*}\phi_j^{(0)}) \tag{47}$$

The divergence of the current is

$$S_i = \partial_\mu j_i^\mu = -2\mathrm{Im}[\epsilon'_i(\partial\phi_i^{(0)*}\phi_j^{(0)} + \partial\phi_j^{(0)*}\phi_i^{(0)})] \tag{48}$$

In obtaining the above expression, we have used the lowest order equation of motion for $\phi_i^{(0)}$. Note that the terms proportional to ϵ_i all canceled out. Only the ϵ_i' terms remain. Therefore the source term is of second order in derivative, which is of the next to leading order compared with the fermionic case. This makes the contribution from boson mixing to be expected less important.

IV. SOURCE TERMS IN DIFFUSION EQUATION

At the semiclassical level the divergence of the currents derived in the previous section can be directly added to the Boltzmann equation as semiclassical sources. In the wall frame the Boltzmann equation has the form

$$\frac{\partial f_i}{\partial t} + \frac{\partial f_i}{\partial z} v_g + \frac{\partial f_i}{\partial p_z} F_{iz} = C[f_i, f_j \cdots] + S_i \tag{49}$$

where $f_i = f_i(t, x, p)$ is the phase space distribution function, C is the collision term and the p_z the kinetic momentum defined by $p_z \equiv \omega v_g$. In a fluid ansatz, the distribution function f_i in the wall frame is

$$f_i = \frac{1}{e^{\beta[\gamma_w(\omega + v_w p_z) - \mu_i(z)]} \pm 1} + \delta f_i(z, p) \tag{50}$$

where the spatially varying chemical potential $\mu_i(z)$ describe the departure from chemical, and the perturbation $\delta f_i(z, p)$ describe the response to the semiclassical force, which by definition has no contribution to the particle density, i.e. $\int d^3p \delta f_i = 0$. The factor $v_w p_z$ comes from the Lorentz boost from the plasma frame to the wall frame. Substituting the distribution function into the Boltzmann equation

$$\frac{\partial f_i}{\partial \omega}\left(v_w F_{iz} - \mu' \frac{p_{zi}}{\omega}\right) + \frac{p_{zi}}{\omega} \delta f_i' = C[f_i, f_j \cdots] + S_i \tag{51}$$

and boosting back into the plasma frame by a Galilean transformation $v_g \to v_g + v_w$ which is valid for small $v_w \ll 1$, we have

$$\left(\frac{p_{iz}}{\omega} + v_w\right)\left(-\mu' \frac{\partial f_{0i}}{\partial \omega} + \delta f_i'\right) + v_w \frac{\partial f_{0i}}{\partial \omega} \delta F_{zi} = C_i^{pl}[\mu_i, \delta f_i] + S_i^{pl} \tag{52}$$

with f_{0i} the up-perturbed Fermi-Dirac distribution $f_0 = (e^{\beta\omega} + 1)^{-1}$ in the plasma frame. The quantity μ_i and δF_{zi} contain only CP violating part of chemical potential and semiclassical force. From Eq.(23), the CP violating force term is

$$\delta F_{zi} = -s \frac{(m_i^2 \mathrm{Im} A_{ii})'}{2\omega^2} \tag{53}$$

The source term S_i^{pl} in the plasma frame is obtained from S_i by a boost $p_z \to p_z + v_w\omega$, namely $S_i^{pl} = S_i(p_z + v_w\omega)$. Note that the p_z-even part in S_i^{pl} only comes from $v_w\omega$ term which is nonvanishing after momentum integration. Thus the source is proportional to the wall velocity v_w and is vanishing in the limit of $v_w \to 0$, which is a physical requirement. Integrating over d^3p weighted by 1 and p_z/ω respectively, we get two transportation equations

$$-v_w\frac{\mu_i^{'}}{T} + \left\langle \frac{p_z}{\omega}\delta f_i^{'} \right\rangle = \left\langle C_i^{pl} \right\rangle + \left\langle S_i^{pl} \right\rangle \tag{54}$$

$$-\frac{\mu^{'}}{T}\left\langle \left(\frac{p_z}{\omega}\right)^2 \right\rangle + v_w\left\langle \frac{p_z}{\omega}\delta f^{'} \right\rangle + \frac{v_w}{T}\left\langle \frac{p_z}{\omega}\delta F_{zi} \right\rangle = \left\langle \frac{p_z}{\omega}C_i^{pl} \right\rangle + \left\langle \frac{p_z}{\omega}S_i^{pl} \right\rangle \tag{55}$$

where the definitions for the integration are [27, 31]

$$\langle X\rangle \equiv k_i\frac{\int d^3p\frac{\partial f_{0i}}{\partial\omega}X}{\int d^3p\frac{\partial f_{0i}}{\partial\omega}}(\text{for } X = \frac{p_z^2}{\omega^2}, \frac{p_z}{\omega}\delta F_{zi}), \text{ and } \langle X\rangle \equiv k_i\frac{\int d^3pX}{T\int d^3p\frac{\partial f_{0i}}{\partial\omega}}, (\ X = \text{others})$$

With the factor $k_i \equiv \int d^3p\frac{\partial f_{0i}}{\partial\omega}/\int d^3p\frac{\partial f_{0i}(m_i=0)}{\partial\omega}$ which is 1(2) for massless fermion(boson). The collision terms can be expressed in terms of chemical potentials and inelastic interaction rates

$$\left\langle C_i^{pl} \right\rangle = -k_i\Gamma_{ik}^d\sum_j \xi_j^{(k)} \quad , \quad \left\langle \frac{p_z}{\omega}C_i^{pl} \right\rangle \simeq k_i\left\langle (p_z/\omega)\delta f_i \right\rangle \Gamma_i^t$$

where Γ_{ik}^d is rate for the inelastic channel (k) and $\sum_j \xi_j^{(k)}$ are the signed sum over the relevant chemical potential. The quantity Γ_i^t is the total interaction rate. Eliminate the quantity $\left\langle \frac{p_z}{\omega}\delta f_i^{'} \right\rangle$ by differentiating the second equation in Eq.(55) once again, one arrives at the usual form of the diffusion equation

$$-k_i\left(D_i\xi_i^{''} + v_w\xi'\right) + \tilde{\Gamma}_{ik}^d\sum_j \xi_j^{(k)} \simeq S_F + S_M$$

with $\tilde{\Gamma}_{ik}^d = k_i\Gamma_{ik}^d$

$$S_F = -\frac{k_iv_wD_i}{T\left\langle \left(\frac{p_z}{\omega}\right)^2 \right\rangle}\left\langle \frac{p_z}{\omega}\delta F_{zi} \right\rangle^{'}, \text{ and } S_M = k_i\left\langle S_i^{pl} \right\rangle$$

where $\xi \equiv \mu_i/T$ the rescaled chemical potential and $D_i = \left\langle (p_z/\omega)^2 \right\rangle/\Gamma_i^t$ the diffusion constant. In deriving the diffusion we have neglected the $\left\langle (p_z/\omega)S_i^{pl} \right\rangle^{'}$ term which is subleading compared with $\left\langle S_i^{pl} \right\rangle$.

V. MIXING INDUCED-SOURCE IN MSSM

In MSSM, the chargino transportation provides a dominant CP violating source to electroweak baryogenesis. The asymmetry in chargino number is converted into the asymmetry in left-handed top quarks through Yukawa interactions. The two Higgsino $SU(2)$ doublets are $\tilde{h}_1 = (\tilde{h}^0_{1L}, \tilde{h}^-_{1L})^T$ and $\tilde{h}_2 = (\tilde{h}^+_{2L}, \tilde{h}^0_{2L})^T$ respectively. Together with the two charged gauginos $\tilde{W}^+_L$ and $\tilde{W}^-_L$, the charginos are combined into two left- and right-handed four component spinors as $\psi_L = (\tilde{W}^+_L, \tilde{h}^+_{2L})^T$ and $\psi_R = ((\tilde{W}^-_L)^c, (\tilde{h}^-_{1L})^c)^T$. The chargino mass term has the form $\bar{\psi}_R M(z) \psi_L$ in the wino-higgsino space with mass matrix

$$M(z) = \begin{pmatrix} M_2 & gH_2(z) \\ gH_1(z) & \mu \end{pmatrix} \tag{56}$$

where M_2 and μ are soft supersymmetry breaking parameters containing CP phases and $H_1(z)$ and $H_2(z)$ the Higgs vacuum expectation values (VEVs). The mass matrix is diagonalized by a bi-unitary transformation $V^\dagger M U$. The explicit form of the two rotation matrices are

$$U = \frac{\sqrt{2}}{\sqrt{\Lambda(\Lambda+\Delta)}} \begin{pmatrix} \frac{1}{2}(\Lambda+\Delta) & -a \\ a^* & \frac{1}{2}(\Lambda+\Delta) \end{pmatrix} \tag{57}$$

$$V = \frac{\sqrt{2}}{\sqrt{\Lambda(\Lambda+\bar{\Delta})}} \begin{pmatrix} \frac{1}{2}(\Lambda+\bar{\Delta}) & -\bar{a} \\ \bar{a}^* & \frac{1}{2}(\Lambda+\bar{\Delta}) \end{pmatrix} \tag{58}$$

with

$$a = M_2 u_1 + \mu^* u_2 \ , \ \bar{a} = M_2^* u_2 + \mu u_1 \tag{59}$$

$$\Delta = |M_2|^2 - |\mu|^2 + u_2^2 - u_1^2 \ , \ \bar{\Delta} = |M_2|^2 - |\mu|^2 - u_2^2 + u_1^2 \tag{60}$$

$$\Lambda = \sqrt{\Delta^2 + 4|a|^2} \ , \ u_i = gH_i(z) \tag{61}$$

The two mass eigenvalues are given by $m_{1,2} = (|M_2|^2 + |\mu|^2 + u_2^2 + u_1^2 \pm \Lambda)/2$. We are interested in the states which is Higgsino-like since only Higgsino can be efficiently transported. The Higgsino-like state is identified as particle 2(1) for parameter region $M_2 > |\mu| (M_2 < |\mu|)$. From the above expression we obtain the off-diagonal elements of matrices Σ and Π which is relevant to the mixing induced source.

$$\Sigma_{12} = -\frac{1}{\Lambda(\Lambda+\Delta)} \left[(\Lambda+\Delta)a' - (\Lambda'+\Delta')a\right] \tag{62}$$

$$\Pi_{12} = -\frac{1}{\Lambda(\Lambda+\bar{\Delta})} \left[(\Lambda+\bar{\Delta})\bar{a}' - (\Lambda'+\bar{\Delta}')\bar{a}\right] \tag{63}$$

the other off-diagonal elements $\Sigma_{21}(\Pi_{21})$ can be easily obtained as $\Sigma(\Pi)$ is anti-Hermitian. The quantity A_{11} relevant to the CP violating force term is given by

$$A_{11} = \frac{M_2 \mu}{m_1^2 \Lambda}(u_1 u_2)'$$

For simplicity, we only consider the chargino contribution as a dominant source, as the transportation for neutrilinos is suppressed due to much weaker couplings to fermions. The stop contributions are also suppressed as they are bosons. Furthermore, the mass difference for the two stops has to be very large. The left-handed stop $\tilde{t}_L$ must be above 1 TeV to evade the LEP experiment constraints [39], while the right-handed stop $\tilde{t}_R$ must be light a round 100 GeV in order to generate strongly first order phase transition [40, 41]. The large mass difference between $\tilde{t}_L$ and $\tilde{t}_R$ leads to a very fast oscillation which strongly suppressed the mixing-induced source in stop sector. As the semiclassical force term does not present in the first order in derivative, we thus neglect the stop contributions.

For numerical illustrations we take the following simple wall profile

$$u(z) = g\sqrt{H_1^2(z) + H_2^2(z)} = g\frac{v_c}{2} \cdot \frac{1}{2}\left[1 - \tanh\left(\frac{z}{L_w}\right)\right]$$

with $H_1(z) = u(z)\sin\beta$ and $H_2(z) = u(z)\cos\beta$ and g the weak gauge coupling. v_c is the Higgs VEV at the critical temperature T which is normalized at $v_{T=0} \simeq 246$ GeV. For numerical calculation we take the following reference values

$$v_c = 120\text{GeV}, T = 90\text{GeV}, \tan\beta = 3, v_w = 0.03$$

We consider different sets of wall-width and MSSM parameters which is sensitive to the mixing-induced source. In Fig.1, we give the source term rescaled by $1/T$ from both semi-classical force and mixing-induced source term for wall width $L_w = 10/T$ and $15/T$ respectively. The MSSM softbreaking parameters are fixed at $M_2 = 200\text{GeV}$ and $|\mu| = 100\text{GeV}$ corresponding to a chargino mass differences $m_1 - m_2 = 111$ GeV in the broken phase. The CP phase ϕ_μ is set to a typical of $\phi_\mu = 0.02$ which is a typically allowed value after the constraints from the electron and Hg electric dipole moments (EDMs) [36, 42, 43]. Note that the EDM constraints on CP phases depends on MSSM parameters such as sfermion masses and CP-odd Higgs masses. For heavy left-handed stop mass above a few TeV as also favored by the LEP limit, the allowed CP phase can be much larger. Furthermore the two-loop corrections to EDM are controlled by CP-odd Higgs mass, which can be weakened

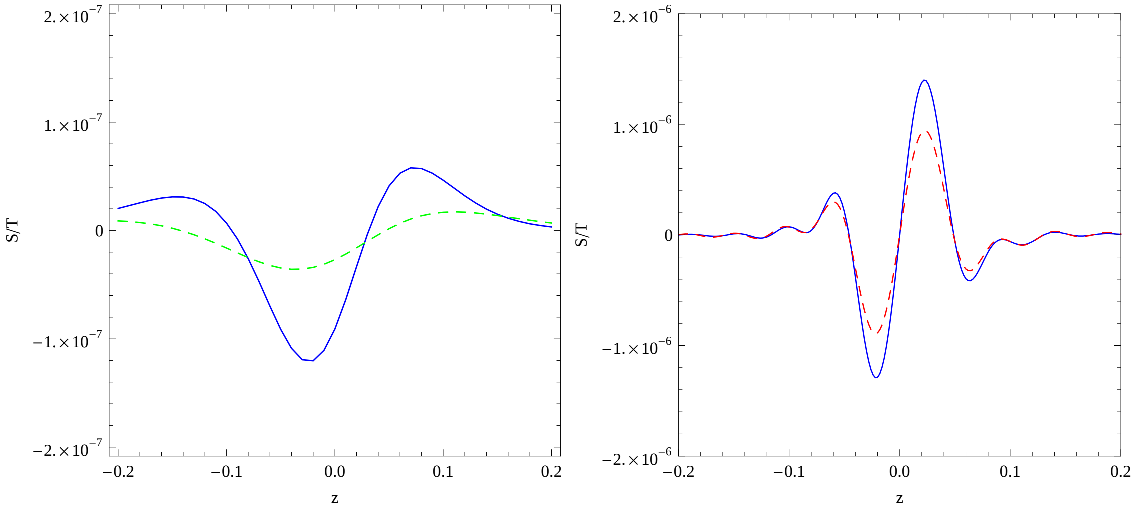

Figure 1: (a)Left, the semiclassical force induced source term as a function of z (GeV^{-1}). (b) Right, the mixing-induced source term as a function of z. The two curves in each plot corresponds to $L_w = 10/T$ (solid) and $15/T$ (dashed) respectively. The MSSM parameters are fixed at $M_2 = 150$ GeV and $\mu = 100$ GeV, with $\phi_\mu = 0.02$.

by heavy Higgs mass, and has no significant effects on the source term. Therefore, although small ϕ_μ is used in the calculation, the possibility of large CP phase close to the maximum may still be allowed in this case. The curves given in Fig.1 show that both of source terms have nontrivial spatial dependencies, but their origin are quite different. The variation of the force term comes from the third derivative of the kink-type Higgs condensate, which has one minimal and two maximums. While the mixing-induced source term varies due to both the wall profile variation and the oscillation. The oscillation leads to multiple local minimum appearing in the curve and is suppressed at large distance by the wall profile. For M_2 around 200 GeV, the mixing induced source term peaks at $z \simeq 0.03$ with an amplitude $S_M/T \simeq 1.6 \times 10^{-6}$, much larger than that from semiclassical force which peaks at $z \simeq 0.08$ with $S_F/T = 0.6 \times 10^{-7}$

In Fig.2, we give the results for a larger $M_2 = 250$ GeV, and still fix $|\mu| = 100$GeV, corresponding to a larger chargino mass differences $m_1 - m_2 = 157$ GeV in the broken phase. One sees that for a larger chargino mass difference both the source terms becomes smaller as they are $1/\Lambda$ suppressed. The oscillation in the mixing-induced source term becomes obvious and the wave length is shorter, thus the oscillation suppression is stronger. The mixing induced source term peaks at $z \simeq 0.03$ with an amplitude $S_M/T \simeq 8 \times 10^{-7}$.

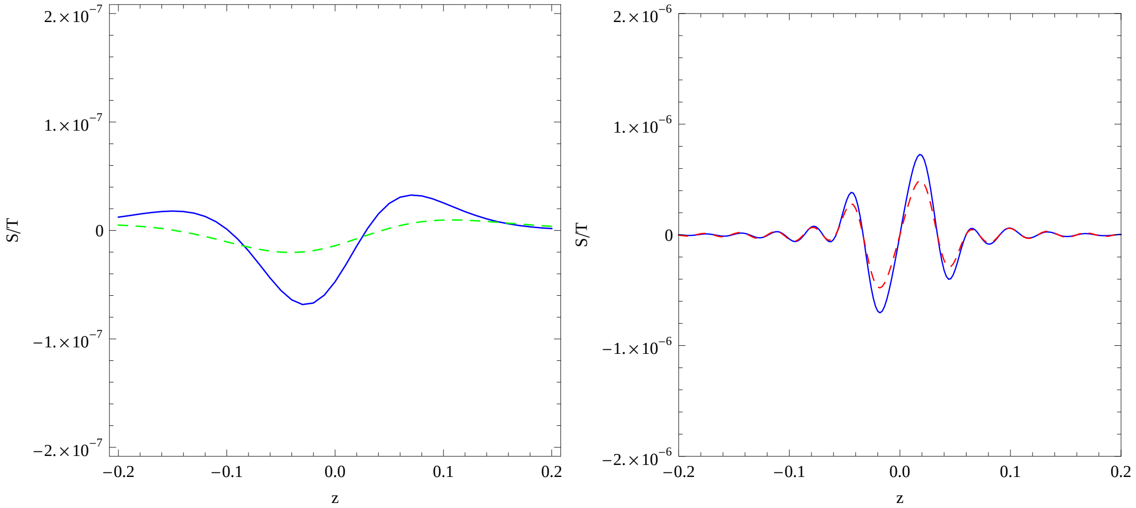

Figure 2: (a)Left, the semiclassical force induced source term as a function of $z(\mathrm{GeV}^{-1})$. (b) Right, the mixing-induced source term as a function of z. The two curves in each plot corresponds to $L_w = 10/T$ (solid) and $15/T$ (dashed) respectively. The MSSM parameters are fixed at $M_2 = 200$ GeV and $\mu = 100$ GeV, with $\phi_\mu = 0.02$.

$M_2(GeV)$	200	250	300	350	450	500
$\bar{S}_M(L_w = 10/T)$	27.5	8.29	3.37	1.50	0.243	0.0364
$\bar{S}_F(L_w = 10/T)$	1.89	1.23	0.822	0.575	0.317	0.246
$\bar{S}_M(L_w = 15/T)$	10.9	5.48	1.45	0.604	0.121	0.0177
$\bar{S}_F(L_w = 15/T)$	0.561	0.365	0.243	0.170	0.094	0.073

Table I: Averaged source term (in unit of 10^{-8}) for mixing induced source and the force term. For wall width $L_w = 10/T$ and $15/T$ respectively.

Although significantly reduced, it still much larger than that from semiclassical force which peaks at $z \simeq 0.08$ with $S_F/T \simeq 4 \times 10^{-8}$.

To estimate the oscillation suppression effects it is useful to define an averaged source over the wall width

$$\bar{S}_{M(F)} \equiv \frac{1}{TL_w}\int_0^{L_w} S_{M(F)}(z)dz \tag{64}$$

We calculate the averaged source numerically for different $M_2 = 200 \sim 500$ GeV and list the results in Tab.I. One sees that $\bar{S}_M$ dominates over $\bar{S}_F$ in the range 200GeV $\lesssim M_2 \lesssim$ 350GeV. With the value of M_2 increasing, the averaged source term $\bar{S}_M$ drops rapidly. For $L_w = 10/T$, at $M_2 = 350$ GeV, the mixing induced source is only 5.4% of that at $M_2 = 200$ GeV, the suppression is due to the increased oscillation frequency. The suppression in force term $\bar{S}_F$ is mainly from the factor $1/\Lambda$, which decreases much slower. At $M_2 = 350$ GeV, it is still about 30% as large as that at $M_2 = 200$ GeV. At $M_2 = 200$ GeV, their relative size is $\bar{S}_M/\bar{S}_F = 14.6$. For large $M_2 = 350$ GeV, although they are close in size, the mixing source still dominates with $\bar{S}_M/\bar{S}_F = 2.63$. This dominance has a mild dependence on the wall width. For $L_w = 15/T$, the relative size between the two kind of sources remains roughly the same, although both of the source term becomes smaller. The mixing-induced source (semiclassical force) term is $\sim 40\%(\sim 30\%)$ of that at $L_w = 10/T$. When the value of M_2 is around 450 GeV, the two type of source term becomes comparable in size. For a very large $M_2 = 500$ GeV, the semiclassical force term becomes dominate, and the mixing-induced source term is about an order of magnitude smaller.

In conclusion, we have studied the effects of flavor mixing in a generalized WKB approach in which the off-diagonal terms in the equation of motion are taken into account as perturbations. With the presence of a slowly moving CP violating bubble wall, an extra mixing-induced CP violating source appears which exhibit an oscillation behavior in analogy to the neutrino mixings. In two flavor mixing case, the oscillation frequency is proportional to the difference of mass square. The size of the mixing-induced source could be larger than that from the conventional semiclassical force as it is at the first order in derivative expansion. We have made a numerical study of the oscillation suppression effects for chargino case in MSSM. For a small $|\mu| = 100$ GeV, in a large range $200 \lesssim M_2 \lesssim 350$ GeV, the mixing -induced source term dominates over the semiclassical force term. The method is valid for small mixing case, a more general method is needed to deal with the maximum mixing case. However, even in the small mixing case the mixing-induced source already indicate that a significant enhancement of the final baryon number asymmetry is possible, which will relax the tension between the observed baryon number asymmetry in the universe and the constraints from electron and atom EDM in the MSSM.
